Multicast Considerations over IEEE 802 Wireless Media

Abstract

Well-known issues with multicast have prevented the deployment of multicast in 802.11 (Wi-Fi) and other local-area wireless environments. This document describes the known limitations of wireless (primarily 802.11) Layer 2 multicast. Also described are certain multicast enhancement features that have been specified by the IETF and by IEEE 802 for wireless media, as well as some operational choices that can be made to improve the performance of the network. Finally, some recommendations are provided about the usage and combination of these features and operational choices.

Status of This Memo

This document is not an Internet Standards Track specification; it is published for informational purposes.

This document is a product of the Internet Engineering Task Force (IETF). It represents the consensus of the IETF community. It has received public review and has been approved for publication by the Internet Engineering Steering Group (IESG). Not all documents approved by the IESG are candidates for any level of Internet Standard; see Section 2 of RFC 7841.

Information about the current status of this document, any errata, and how to provide feedback on it may be obtained at <https://www.rfc-editor.org/info/rfc9119>.

1. Introduction

Well-known issues with multicast have prevented the deployment of multicast in 802.11 [dot11] and other local-area wireless environments, as described in [mc-props] and [mc-prob-stmt]. Performance issues have been observed when multicast packet transmissions of IETF protocols are used over IEEE 802 wireless media. Even though enhancements for multicast transmissions have been designed at both IETF and IEEE 802, incompatibilities still exist between specifications, implementations, and configuration choices.

Many IETF protocols depend on multicast/broadcast for delivery of control messages to multiple receivers. Multicast allows data to be sent to multiple interested recipients without the source needing to

send duplicate data to each recipient. With broadcast traffic, data is sent to every device regardless of their expressed interest in the data. Multicast is used for various purposes such as Neighbor Discovery, network flooding, and address resolution, as well as minimizing media occupancy for the transmission of data that is intended for multiple receivers. In addition to protocol use of broadcast/multicast for control messages, more applications, such as Push To Talk in hospitals or video in enterprises, universities, and homes, are sending multicast IP to end-user devices, which are increasingly using Wi-Fi for their connectivity.

IETF protocols typically rely on network protocol layering in order to reduce or eliminate any dependence of higher-level protocols on the specific nature of the MAC-layer protocols or the physical media. In the case of multicast transmissions, higher-level protocols have traditionally been designed as if transmitting a packet to an IP address had the same cost in interference and network media access, regardless of whether the destination IP address is a unicast address or a multicast or broadcast address. This model was reasonable for networks where the physical medium was wired, like Ethernet. Unfortunately, for many wireless media, the costs to access the medium can be quite different. Multicast over Wi-Fi has often been plagued by such poor performance that it is disallowed. Some enhancements have been designed in IETF protocols that are assumed to work primarily over wireless media. However, these enhancements are usually implemented in limited deployments and are not widespread on most wireless networks.

IEEE 802 wireless protocols have been designed with certain features to support multicast traffic. For instance, lower modulations are used to transmit multicast frames so that these can be received by all stations in the cell, regardless of the distance or path attenuation from the base station or Access Point (AP). However, these lower modulation transmissions occupy the medium longer; they hamper efficient transmission of traffic using higher-order modulations to nearby stations. For these and other reasons, IEEE 802 Working Groups such as 802.11 have designed features to improve the performance of multicast transmissions at Layer 2 [ietf_802-11]. In addition to protocol design features, certain operational and configuration enhancements can ameliorate the network performance issues created by multicast traffic, as described in Section 5.

There seems to be general agreement that these problems will not be fixed anytime soon, primarily because it's expensive to do so and because of the unreliability of multicast. Compared to unicast over Wi-Fi, multicast is often treated as somewhat of a second-class citizen even though there are many protocols using multicast. Something needs to be provided in order to make them more reliable. IPv6 Neighbor Discovery saturating the Wi-Fi link is only part of the problem. Wi-Fi traffic classes may help. This document is intended to help make the determination about what problems should be solved by the IETF and what problems should be solved by the IEEE (see Section 8).

This document details various problems caused by multicast transmission over wireless networks, including high packet error

rates, no acknowledgements, and low data rate. It also explains some enhancements that have been designed at the IETF and IEEE 802.11 to ameliorate the effects of the radio medium on multicast traffic. Recommendations are also provided to implementors about how to use and combine these enhancements. Some advice about the operational choices that can be made is also included. It is likely that this document will also be considered relevant to designers of future IEEE wireless specifications.

2. Terminology

This document uses the following definitions:

ACK

The 802.11 Layer 2 acknowledgement.

AES-CCMP

AES-Counter Mode CBC-MAC Protocol

AP

IEEE 802.11 Access Point.

Basic rate

The slowest rate of all the connected devices at which multicast and broadcast traffic is generally transmitted.

DVB-H

Digital Video Broadcasting - Handheld

DVB-IPDC

Digital Video Broadcasting - Internet Protocol Datacasting

DTIM

Delivery Traffic Indication Map; an information element that advertises whether or not any associated stations have buffered multicast or broadcast frames.

MCS

Modulation and Coding Scheme.

NOC

Network Operations Center.

PER

Packet Error Rate.

STA

802.11 station (e.g., handheld device).

TIM

Traffic Indication Map; an information element that advertises whether or not any associated stations have buffered unicast frames.

TKIP

Temporal Key Integrity Protocol

WiMAX

Worldwide Interoperability for Microwave Access

WPA

Wi-Fi Protected Access

3. Identified Multicast Issues

3.1. Issues at Layer 2 and Below

In this section, some of the issues related to the use of multicast transmissions over IEEE 802 wireless technologies are described.

3.1.1. Multicast Reliability

Multicast traffic is typically much less reliable than unicast traffic. Since multicast makes point-to-multipoint communications, multiple acknowledgements would be needed to guarantee reception at all recipients. However, since there are no ACKs for multicast packets, it is not possible for the AP to know whether or not a retransmission is needed. Even in the wired Internet, this characteristic often causes undesirably high error rates. This has contributed to the relatively slow uptake of multicast applications even though the protocols have long been available. The situation for wireless links is much worse and is quite sensitive to the presence of background traffic. Consequently, there can be a high packet error rate (PER) due to lack of retransmission and because the sender never backs off. PER is the ratio, in percent, of the number of packets not successfully received by the device. It is not uncommon for there to be a packet loss rate of 5% or more, which is particularly troublesome for video and other environments where high data rates and high reliability are required.

3.1.2. Lower and Variable Data Rate

Multicast over wired differs from multicast over wireless because transmission over wired links often occurs at a fixed rate. Wi-Fi, on the other hand, has a transmission rate that varies depending upon the STA's proximity to the AP. The throughput of video flows and the capacity of the broader Wi-Fi network will change with device movement. This impacts the ability for QoS solutions to effectively reserve bandwidth and provide admission control.

For wireless stations authenticated and linked with an AP, the power necessary for good reception can vary from station to station. For unicast, the goal is to minimize power requirements while maximizing the data rate to the destination. For multicast, the goal is simply to maximize the number of receivers that will correctly receive the multicast packet; generally, the AP has to use a much lower data rate at a power level high enough for even the farthest station to receive the packet, for example, as briefly mentioned in Section 4 of [RFC5757]. Consequently, the data rate of a video stream, for instance, would be constrained by the environmental considerations of the least-reliable receiver associated with the AP.

Because more robust modulation and coding schemes (MCSs) have a longer range but also a lower data rate, multicast/broadcast traffic is generally transmitted at the slowest rate of all the connected devices. This is also known as the basic rate. The amount of additional interference depends on the specific wireless technology. In fact, backward compatibility and multi-stream implementations mean that the maximum unicast rates are currently up to a few Gbps, so there can be more than 3 orders of magnitude difference in the transmission rate between multicast/broadcast versus optimal unicast forwarding. Some techniques employed to increase spectral efficiency, such as spatial multiplexing in Multiple Input Multiple Output (MIMO) systems, are not available with more than one intended receiver; it is not the case that backwards compatibility is the only factor responsible for lower multicast transmission rates.

Wired multicast also affects wireless LANs when the AP extends the wired segment; in that case, multicast/broadcast frames on the wired LAN side are copied to the Wireless Local Area Network (WLAN). Since broadcast messages are transmitted at the most robust MCS, many large frames are sent at a slow rate over the air.

3.1.3. Capacity and Impact on Interference

Transmissions at a lower rate require longer occupancy of the wireless medium and thus take away from the airtime of other communications and degrade the overall capacity. Furthermore, transmission at higher power, as is required to reach all multicast STAs associated with the AP, proportionately increases the area of interference with other consumers of the radio spectrum.

3.1.4. Power-Save Effects on Multicast

One of the characteristics of multicast transmission over Wi-Fi is that every station has to be configured to wake up to receive the multicast frame, even though the received packet may ultimately be discarded. This process can have a large effect on the power consumption by the multicast receiver station. For this reason, there are workarounds, such as Directed Multicast Service (DMS) described in Section 4, to prevent unnecessarily waking up stations.

Multicast (and unicast) can work poorly with the power-save mechanisms defined in IEEE 802.11e for the following reasons.

- * Clients may be unable to stay in sleep mode due to multicast control packets frequently waking them up.
- * A unicast packet is delayed until an STA wakes up and requests it. Unicast traffic may also be delayed to improve power save and efficiency and to increase the probability of aggregation.
- * Multicast traffic is delayed in a wireless network if any of the STAs in that network are power savers. All STAs associated with the AP have to be awake at a known time to receive multicast traffic.
- * Packets can also be discarded due to buffer limitations in the AP

and non-AP STA.

3.2. Issues at Layer 3 and Above

This section identifies some representative IETF protocols and describes possible negative effects due to performance degradation when using multicast transmissions for control messages. Common uses of multicast include:

- * Control plane signaling
- * Neighbor Discovery
- * Address resolution
- * Service Discovery
- * Applications (video delivery, stock data, etc.)
- * On-demand routing
- * Backbone construction
- * Other Layer 3 protocols (non-IP)

User Datagram Protocol (UDP) is the most common transport-layer protocol for multicast applications. By itself, UDP is not reliable -- messages may be lost or delivered out of order.

3.2.1. IPv4 Issues

The following list contains some representative discovery protocols that utilize broadcast/multicast and are used with IPv4.

- * ARP [RFC0826]
- * DHCP [RFC2131]
- * Multicast DNS (mDNS) [RFC6762]
- * Universal Plug and Play (uPnP) [RFC6970]

After initial configuration, ARP (described in more detail later), DHCP, and uPnP occur much less commonly, but service discovery can occur at any time. Some widely deployed service discovery protocols (e.g., for finding a printer) utilize mDNS (i.e., multicast), which is often dropped by operators. Even if multicast snooping [RFC4541] (which provides the benefit of conserving bandwidth on those segments of the network where no node has expressed interest in receiving packets addressed to the group address) is utilized, many devices can register at once and cause serious network degradation.

3.2.2. IPv6 Issues

IPv6 makes extensive use of multicast, including the following:

- * DHCPv6 [RFC8415]
- * Protocol Independent Multicast (PIM) [RFC7761]
- * IPv6 Neighbor Discovery Protocol (NDP) [RFC4861]
- * Multicast DNS (mDNS) [RFC6762]
- * Router Discovery [RFC4286]

IPv6 NDP Neighbor Solicitation (NS) messages used in Duplicate Address Detection (DAD) and address lookup make use of link-scope multicast. In contrast to IPv4, an IPv6 node will typically use multiple addresses and may change them often for privacy reasons. This intensifies the impact of multicast messages that are associated with the mobility of a node. Router advertisement (RA) messages are also periodically multicast over the link.

Neighbors may be considered lost if several consecutive Neighbor Discovery packets fail.

3.2.3. MLD Issues

Multicast Listener Discovery (MLD) [RFC4541] is used to identify members of a multicast group that are connected to the ports of a switch. Forwarding multicast frames into a Wi-Fi-enabled area can use switch support for hardware forwarding state information. However, since IPv6 makes heavy use of multicast, each STA with an IPv6 address will require state on the switch for several and possibly many solicited-node multicast addresses. A solicited-node multicast address is an IPv6 multicast address used by NDP to verify whether an IPv6 address is already used by the local link. Multicast addresses that do not have forwarding state installed (perhaps due to hardware memory limitations on the switch) cause frames to be flooded on all ports of the switch. Some switch vendors do not support MLD for link-scope multicast due to the increase it can cause in state.

3.2.4. Spurious Neighbor Discovery

On the Internet, there is a "background radiation" of scanning traffic (people scanning for vulnerable machines) and backscatter (responses from spoofed traffic, etc.). This means that routers very often receive packets destined for IPv4 addresses regardless of whether those IP addresses are in use. In the cases where the IP is assigned to a host, the router broadcasts an ARP request, receives an ARP reply, and caches it; then, traffic can be delivered to the host. When the IP address is not in use, the router broadcasts one (or more) ARP requests and never gets a reply. This means that it does not populate the ARP cache, and the next time there is traffic for that IP address, the router will rebroadcast the ARP requests.

The rate of these ARP requests is proportional to the size of the subnets, the rate of scanning and backscatter, and how long the router keeps state on non-responding ARPs. As it turns out, this rate is inversely proportional to how occupied the subnet is (valid ARPs end up in a cache, stopping the broadcasting; unused IPs never

respond, and so cause more broadcasts). Depending on the address space in use, the time of day, how occupied the subnet is, and other unknown factors, thousands of broadcasts per second have been observed. Around 2,000 broadcasts per second have been observed at the IETF NOC during face-to-face meetings.

With Neighbor Discovery for IPv6 [RFC4861], nodes accomplish address resolution by multicasting a Neighbor Solicitation that asks the target node to return its link-layer address. Neighbor Solicitation messages are multicast to the solicited-node multicast address of the target address. The target returns its link-layer address in a unicast Neighbor Advertisement message. A single request-response pair of packets is sufficient for both the initiator and the target to resolve each other's link-layer addresses; the initiator includes its link-layer address in the Neighbor Solicitation.

On a wired network, there is not a huge difference between unicast, multicast, and broadcast traffic. Due to hardware filtering (see, e.g., [Deri-2010]), inadvertently flooded traffic (or excessive Ethernet multicast) on wired networks can be quite a bit less costly compared to wireless cases where sleeping devices have to wake up to process packets. Wired Ethernets tend to be switched networks, further reducing interference from multicast. There is effectively no collision / scheduling problem except at extremely high port utilizations.

This is not true in the wireless realm; wireless equipment is often unable to send high volumes of broadcast and multicast traffic, causing numerous broadcast and multicast packets to be dropped. Consequently, when a host connects, it is often not able to complete DHCP, and IPv6 RAs get dropped, leading to users being unable to use the network.

4. Multicast Protocol Optimizations

This section lists some optimizations that have been specified in IEEE 802 and IETF that are aimed at reducing or eliminating the issues discussed in Section 3.

4.1. Proxy ARP in 802.11-2012

The AP knows the Medium Access Control (MAC) address and IP address for all associated STAs. In this way, the AP acts as the central "manager" for all the 802.11 STAs in its Basic Service Set (BSS). Proxy ARP is easy to implement at the AP and offers the following advantages:

- * Reduced broadcast traffic (transmitted at low MCS) on the wireless medium.
- * STA benefits from extended power save in sleep mode, as ARP requests for STA's IP address are handled instead by the AP.
- * ARP frames are kept off the wireless medium.
- * No changes are needed to STA implementation.

Here is the specification language as described in clause 10.23.13 of [dot11-proxyarp]:

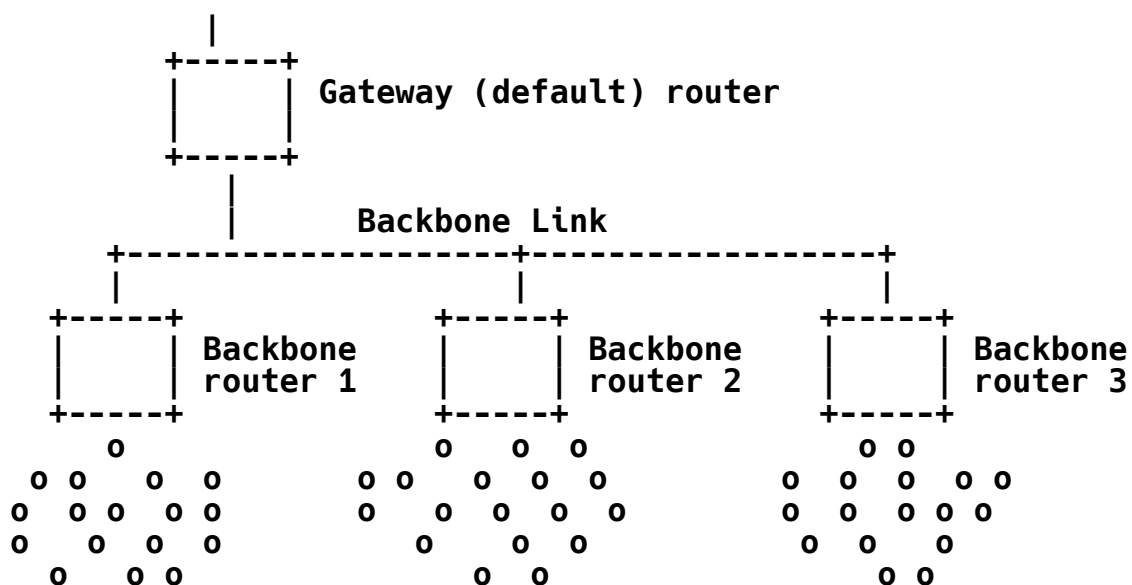

When the AP supports Proxy ARP "[...] the AP shall maintain a Hardware Address to Internet Address mapping for each associated station, and shall update the mapping when the Internet Address of the associated station changes. When the IPv4 address being resolved in the ARP request packet is used by a non-AP STA currently associated to the BSS, the proxy ARP service shall respond on behalf of the STA to an ARP request or an ARP Probe.

4.2. IPv6 Address Registration and Proxy Neighbor Discovery

As used in this section, a Low-Power Wireless Personal Area Network (6LoWPAN) denotes a Low-Power and Lossy Network (LLN) that supports 6LoWPAN Header Compression (HC) [RFC6282]. A 6TiSCH network [RFC9030] is an example of a 6LoWPAN. In order to control the use of IPv6 multicast over 6LoWPANs, the 6LoWPAN Neighbor Discovery (6LoWPAN ND) [RFC6775] standard defines an address registration mechanism that relies on a central registry to assess address uniqueness as a substitute to the inefficient DAD mechanism found in the mainstream IPv6 Neighbor Discovery Protocol (NDP) [RFC4861] [RFC4862].

The 6lo Working Group has specified an update to [RFC6775]. Wireless devices can register their address to a Backbone Router [RFC8929], which proxies for the registered addresses with the IPv6 NDP running on a high-speed aggregating backbone. The update also enables a proxy registration mechanism on behalf of the Registered Node, e.g., by a 6LoWPAN router to which the mobile node is attached.

The general idea behind the Backbone Router concept is that broadcast and multicast messaging should be tightly controlled in a variety of WLANs and Wireless Personal Area Networks (WPANs). Connectivity to a particular link that provides the subnet should be left to Layer 3. The model for the Backbone Router operation is represented in Figure 1.

LLN 1

LLN 2

LLN 3

Figure 1: Backbone Link and Backbone Routers

LLN nodes can move freely from an LLN anchored at one IPv6 Backbone Router to an LLN anchored at another Backbone Router on the same backbone, keeping any of the IPv6 addresses they have configured. The Backbone Routers maintain a Binding Table of their Registered Nodes, which serves as a distributed database of all the LLN nodes. An extension to the Neighbor Discovery Protocol is introduced to exchange Binding Table information across the Backbone Link as needed for the operation of IPv6 Neighbor Discovery.

[RFC6775] and follow-on work [RFC8505] address the needs of LLNs, and similar techniques are likely to be valuable on any type of link where sleeping devices are attached or where the use of broadcast and multicast operations should be limited.

4.3. Buffering to Improve Battery Life

Methods have been developed to help save battery life; for example, a device might not wake up when the AP receives a multicast packet. The AP acts on behalf of STAs in various ways. To enable use of the power-saving feature for STAs in its BSS, the AP buffers frames for delivery to the STA at the time when the STA is scheduled for reception. If an AP, for instance, expresses a Delivery Traffic Indication Message (DTIM) of 3, then the AP will send a multicast packet every 3 packets. In fact, when any single wireless STA associated with an AP has 802.11 power-save mode enabled, the AP buffers all multicast frames and sends them only after the next DTIM beacon.

In practice, most APs will send a multicast every 30 packets. For unicast, the AP could send a Traffic Indication Message (TIM), but, for multicast, the AP sends a broadcast to everyone. DTIM does power management, but STAs can choose whether to wake up and whether to drop the packet. Unfortunately, without proper administrative control, such STAs may be unable to determine why their multicast operations do not work.

4.4. Limiting Multicast Buffer Hardware Queue Depth

The Content after Beacon (CAB) queue is used for beacon-triggered transmission of buffered multicast frames. If lots of multicast frames were buffered and this queue fills up, it drowns out all regular traffic. To limit the damage that buffered traffic can do, some drivers limit the amount of queued multicast data to a fraction of the beacon_interval. An example of this is [CAB].

4.5. IPv6 Support in 802.11-2012

IPv6 uses NDP instead of ARP. Every IPv6 node subscribes to a special multicast address for this purpose.

Here is the specification language from clause 10.23.13 of

[dot11-proxyarp]:

When an IPv6 address is being resolved, the Proxy Neighbor Discovery service shall respond with a Neighbor Advertisement message [...] on behalf of an associated STA to an [ICMPv6] Neighbor Solicitation message [...]. When MAC address mappings change, the AP may send unsolicited Neighbor Advertisement Messages on behalf of a STA.

NDP may be used to request additional information using the following methods, among others:

- * Maximum Transmission Unit
- * Router Solicitation
- * Router Advertisement

NDP messages are sent as group-addressed (broadcast) frames in 802.11. Using the proxy operation helps to keep NDP messages off the wireless medium.

4.6. Using Unicast Instead of Multicast

It is often possible to transmit multicast control and data messages by using unicast transmissions to each station individually.

4.6.1. Overview

In many situations, it's a good choice to use unicast instead of multicast over the Wi-Fi link. This avoids most of the problems specific to multicast over Wi-Fi, since the individual frames are then acknowledged and buffered for power-save clients in the way that unicast traffic normally operates.

This approach comes with the trade-off of sometimes sending the same packet multiple times over the Wi-Fi link. However, in many cases, such as video into a residential home network, this can be a good trade-off since the Wi-Fi link may have enough capacity for the unicast traffic to be transmitted to each subscribed STA, even though multicast addressing may have been necessary for the upstream access network.

Several technologies exist that can be used to arrange unicast transport over the Wi-Fi link, outlined in the subsections below.

4.6.2. Layer 2 Conversion to Unicast

It is often possible to transmit multicast control and data messages by using unicast transmissions to each station individually.

Although there is not yet a standardized method of conversion, at least one widely available implementation exists in the Linux bridging code [bridge-mc-2-uc]. Other proprietary implementations are available from various vendors. In general, these implementations perform a straightforward mapping for groups or

channels, discovered by IGMP or MLD snooping, to the corresponding unicast MAC addresses.

4.6.3. Directed Multicast Service (DMS)

DMS enables an STA to request that the AP transmit multicast group-addressed frames destined to the requesting STAs as individually addressed frames (i.e., convert multicast to unicast). Here are some characteristics of DMS:

- * Requires 802.11n Aggregate MAC Service Data Units (A-MSDUs).
- * Individually addressed frames are acknowledged and are buffered for power-save STAs.
- * The requesting STA may specify traffic characteristics for DMS traffic.
- * DMS was defined in IEEE Std 802.11v-2011 [v2011].
- * DMS requires changes to both AP and STA implementation.

DMS is not currently implemented in products. See [Tramarin2017] and [Oliva2013] for more information.

4.6.4. Automatic Multicast Tunneling (AMT)

AMT [RFC7450] provides a method to tunnel multicast IP packets inside unicast IP packets over network links that only support unicast. When an operating system or application running on an STA has an AMT gateway capability integrated, it's possible to use unicast to traverse the Wi-Fi link by deploying an AMT relay in the non-Wi-Fi portion of the network connected to the AP.

It is recommended that multicast-enabled networks deploying AMT relays for this purpose make the relays locally discoverable with the following methods, as described in [RFC8777]:

- * DNS-based Service Discovery (DNS-SD) [RFC6763]
- * The well-known IP addresses from Section 7 of [RFC7450]

An AMT gateway that implements multiple standard discovery methods is more likely to discover the local multicast-capable network instead of forming a connection to a nonlocal AMT relay further upstream.

4.7. GroupCast with Retries (GCR)

GCR (defined in [dot11aa]) provides greater reliability by using either unsolicited retries or a block acknowledgement mechanism. GCR increases the probability of broadcast frame reception success but still does not guarantee success.

For the block acknowledgement mechanism, the AP transmits each group-addressed frame as a conventional group-addressed transmission. Retransmissions are group addressed but hidden from non-11aa STAs. A

directed block acknowledgement scheme is used to harvest reception status from receivers; retransmissions are based upon these responses.

GCR is suitable for all group sizes including medium to large groups. As the number of devices in the group increases, GCR can send block acknowledgement requests to only a small subset of the group. GCR does require changes to both AP and STA implementations.

GCR may introduce unacceptable latency. After sending a group of data frames to the group, the AP has to do the following:

- * Unicast a Block Ack Request (BAR) to a subset of members.
- * Wait for the corresponding Block Ack (BA).
- * Retransmit any missed frames.
- * Resume other operations that may have been delayed.

This latency may not be acceptable for some traffic.

There are ongoing extensions in 802.11 to improve GCR performance.

- * BAR is sent using downlink Multi-User MIMO.
- * BA is sent using uplink MU-MIMO (uplink MU-MIMO is an IEEE 801.11ax-2021 feature).
- * Latency may also be reduced by simultaneously receiving BA information from multiple STAs.

5. Operational Optimizations

This section lists some operational optimizations that can be implemented when deploying wireless IEEE 802 networks to mitigate some of the issues discussed in Section 3.

5.1. Mitigating Problems from Spurious Neighbor Discovery

ARP Sponges

An ARP Sponge sits on a network and learns which IP addresses are actually in use. It also listens for ARP requests, and, if it sees an ARP for an IP address that it believes is not used, it will reply with its own MAC address. This means that the router now has an IP-to-MAC mapping, which it caches. If that IP is later assigned to a machine (e.g., using DHCP), the ARP Sponge will see this and will stop replying for that address. Gratuitous ARPs (or the machine ARPing for its gateway) will replace the sponged address in the router ARP table. This technique is quite effective; unfortunately, the ARP Sponge daemons were not really designed for this use (one of the most widely deployed ARP Sponges [arpsponge] was designed to deal with the disappearance of participants from an Internet Exchange Point (IXP)) and so are not optimized for this purpose. One daemon is needed per subnet; the tuning is tricky

(the scanning rate versus the population rate versus retries, etc.), and sometimes daemons just stop, requiring a restart of the daemon that causes disruption.

Router mitigations

Some routers (often those based on Linux) implement a "negative ARP cache" daemon. If the router does not see a reply to an ARP, it can be configured to cache this information for some interval. Unfortunately, the core routers in use often do not support this. Instead, when a host connects to a network and gets an IP address, it will ARP for its default gateway (the router). The router will update its cache with the IP to host MAC mapping learned from the request (passive ARP learning).

Firewall unused space

The distribution of users on wireless networks / subnets may change in various use cases, such as conference venues (e.g., Service Set Identifiers (SSIDs) are renamed, some SSIDs lose favor, etc.). This makes utilization for particular SSIDs difficult to predict ahead of time, but usage can be monitored as attendees use the different networks. Configuring multiple DHCP pools per subnet and enabling them sequentially can create a large subnet from which only addresses in the lower portions are assigned. Therefore, input IP access lists can be applied, which deny traffic to the upper, unused portions. Then the router does not attempt to forward packets to the unused portions of the subnets and so does not ARP for it. This method has proven to be very effective but is somewhat of a blunt axe, is fairly labor intensive, and requires coordination.

Disabling/Filtering ARP requests

In general, the router does not need to ARP for hosts; when a host connects, the router can learn the IP-to-MAC mapping from the ARP request sent by that host. Consequently, it should be possible to disable and/or filter ARP requests from the router. Unfortunately, ARP is a very low-level/fundamental part of the IP stack and is often offloaded from the normal control plane. While many routers can filter Layer 2 traffic, this is usually implemented as an input filter and/or has limited ability to filter output broadcast traffic. This means that the seemingly simple and obvious solution to "just disable ARP or filter it outbound" is made difficult or awkward in practice by implementations and/or architectural issues.

NAT

Broadcasts can often be caused by outside Wi-Fi scanning / backscatter traffic. In order to reduce the impact of broadcasts, NAT can be used on the entire (or a large portion) of a network. This would eliminate NAT translation entries for unused addresses, and the router would never ARP for them. There are, however, many reasons to avoid using NAT in such a blanket fashion.

Stateful firewalls

Another obvious solution would be to put a stateful firewall

between the wireless network and the Internet. This firewall would block incoming traffic not associated with an outbound request. But this conflicts with the need and desire of some organizations to have the network as open as possible and to honor the end-to-end principle. An attendee on a meeting network should be an Internet host and should be able to receive unsolicited requests. Unfortunately, keeping the network working and stable is the first priority, and a stateful firewall may be required in order to achieve this.

5.2. Mitigating Spurious Service Discovery Messages

In networks that must support hundreds of STAs, operators have observed network degradation due to many devices simultaneously registering with mDNS. In a network with many clients, it is recommended to ensure that mDNS packets designed to discover services in smaller home networks be constrained to avoid disrupting other traffic.

6. Multicast Considerations for Other Wireless Media

Many of the causes of performance degradation described in earlier sections are also observable for wireless media other than 802.11.

For instance, problems with power save, excess media occupancy, and poor reliability will also affect 802.15.3 and 802.15.4. Unfortunately, 802.15 media specifications do not yet include mechanisms similar to those developed for 802.11. In fact, the design philosophy for 802.15 is oriented towards minimality, with the result that many such functions are relegated to operation within higher-layer protocols. This leads to a patchwork of non-interoperable and vendor-specific solutions. See [uli] for additional discussion and a proposal for a task group to resolve similar issues, in which the multicast problems might be considered for mitigation.

Similar considerations hold for most other wireless media. A brief introduction is provided in [RFC5757] for the following:

- * 802.16 WiMAX
- * 3GPP/3GPP2
- * DVB-H/DVB-IPDC
- * TV Broadcast and Satellite Networks

7. Recommendations

This section provides some recommendations about the usage and combinations of some of the multicast enhancements described in Sections 4 and 5.

Future protocol documents utilizing multicast signaling should be carefully scrutinized if the protocol is likely to be used over wireless media.

The use of proxy methods should be encouraged to conserve network bandwidth and power utilization by low-power devices. The device can send a unicast message to its proxy, and then the proxy can take care of any needed multicast operations.

Multicast signaling for wireless devices should be done in a way that is compatible with low duty-cycle operation.

8. Ongoing Discussion Items

This section suggests two discussion items for further resolution.

First, standards (and private) organizations should develop guidelines to help clarify when multicast packets would be better served by being sent wired rather than wireless. For example, 802.1ak [IEEE802.1ak] works on both Ethernet and Wi-Fi, and organizations could help with deployment decision making by developing guidelines for multicast over Wi-Fi, including options for when traffic should be sent wired.

Second, reliable registration to Layer 2 multicast groups and a reliable multicast operation at Layer 2 might provide a good multicast over Wi-Fi solution. There shouldn't be a need to support 2^{24} groups to get solicited node multicast working: it is possible to simply select a number of bits that make sense for a given network size to limit the number of unwanted deliveries to reasonable levels. The IEEE 802.1, 802.11, and 802.15 Working Groups should be encouraged to revisit Layer 2 multicast issues and provide workable solutions.

9. Security Considerations

This document does not introduce or modify any security mechanisms. Multicast deployed on wired or wireless networks as discussed in this document can be made more secure in a variety of ways. [RFC4601], for instance, specifies the use of IPsec to ensure authentication of the link-local messages in the Protocol Independent Multicast - Sparse Mode (PIM-SM) routing protocol. [RFC5796] specifies mechanisms to authenticate the PIM-SM link-local messages using the IP security (IPsec) Encapsulating Security Payload (ESP) or (optionally) the Authentication Header (AH).

When using mechanisms that convert multicast traffic to unicast traffic for traversing radio links, the AP (or other entity) is forced to explicitly track which subscribers care about certain multicast traffic. This is generally a reasonable trade-off but does result in another entity that is tracking what entities subscribe to which multicast traffic. While such information is already (by necessity) tracked elsewhere, this does present an expansion of the attack surface for that potentially privacy-sensitive information.

As noted in [group_key], the unreliable nature of multicast transmission over wireless media can cause subtle problems with multicast group key management and updates. [group_key] states that when TKIP (WPA, now deprecated) or AES-CCMP (WPA2/WPA3) encryption is

in use, AP-to-client (FromDS) multicasts have to be encrypted with a separate encryption key that is known to all of the clients (this is called the Group Key). Quoting further from that website, "... most clients are able to get connected and surf the web, check email, etc. even when FromDS multicasts are broken. So a lot of people don't realize they have multicast problems on their network..."

This document encourages the use of proxy methods to conserve network bandwidth and power utilization by low-power devices. Such proxy methods in general have security considerations that require the proxy to be trusted to not misbehave. One such proxy method listed is an ARP Sponge that listens for ARP requests, and, if it sees an ARP for an IP address that it believes is not used, it will reply with its own MAC address. ARP poisoning and false advertising could potentially undermine (e.g., DoS) this and other proxy approaches.

10. IANA Considerations

This document has no IANA actions.
